Abstract—We consider spatial interference mitigation at the transmitter for multiple input single output ad hoc networks. We apply zero forcing beamforming at the transmitter, and analyze the corresponding network throughput and transmission capacity. Assuming a network with Poisson distributed transmitting nodes and spatially independent Rayleigh fading channels, we apply mathematical tools from stochastic geometry to derive a lower bound on the probability of outage. We derive scaling laws for the transmission capacity and show that for a large number of antennas, the maximum density of concurrently transmitting nodes scales linearly with the number of antennas at the transmitter, for a given outage constraint. Numerical results show that the network throughput achieved by interference nulling at the transmitter is comparable to that achieved by interference cancellation at the receiver.

I. INTRODUCTION

Mutual interference poses a major bottleneck on the throughput performance of mobile ad hoc networks. Employing multiple antennas at the radio nodes is a promising technique to mitigate interference and increase the network throughput. In particular, multiple antenna processing techniques at the receiver have been shown to yield linear performance in terms of maximum density scaling [1]. The role of multiple antennas in interference nulling at the transmitter, however, have not yet been fully investigated. This paper analyzes the gains from using multiple antennas for transmission in an ad hoc network. It applies transmit zero forcing beamforming for a multiple input single output (MISO) ad hoc network to increase the density of successful communication links.

Multiple antenna techniques for both single-user and multi-user multiple systems have been investigated in the literature [1]–[9] of mobile ad hoc networks. Single antenna transmission with multiple antennas interference cancellation at the

receiver was shown in [1] to achieve linear scaling of the maximum density of transmitting nodes with the number of antennas at the receiver. Maximum ratio transmission and zero forcing beamforming towards the strongest interferers at the receivers was analyzed in [3]. Outage probability and density scaling results for maximum ratio transmission and maximum ratio combining was reported in [6]. Open loop transmission with spatial multiplexing and orthogonal space time block codes and linear receivers was analyzed in [4]. The performance of multi-user MIMO communication in a Poisson field of interferers, with full and partial CSI at the transmitter was investigated in [7], [8]; it was shown that single-user transmission is optimal for most practical scenarios of interest. Multiple antenna interference nulling was considered in [9] for a two-tier spectrum sharing ad hoc network. Full zero forcing from the secondary network towards the primary receivers was applied at the transmitter. Using multiple antennas at the transmitter for same-tier interference mitigation was, however, not investigated. Prior work on spatial interference mitigation for same-tier mobile ad hoc networks [1]–[4] focused exclusively on multiple antenna processing at the receiver. Multiple antennas at the transmitter, if present, were used for maximum ratio transmission or open loop spatial loop multiplexing towards the associated receiver. The role of multiple antennas in interference mitigation at the transmitter was not considered.

Assuming the transmitter locations are distributed according to a homogeneous Poisson point process (PPP), we focus in this paper on devising a strategy to use multiple antennas for interference mitigation at the transmitter, to maximize the network throughput and increase the density of concurrently transmitting nodes. We consider a mobile ad hoc network with single-stream data links and single receive antennas. We apply zero forcing (ZF) to null the interference from the transmitters at the closest receivers. We derive bounds on the resulting probability of outage and the network throughput of the mobile ad hoc network. We derive the scaling law of the transmission capacity with the number of transmit antennas, for sufficiently large number of antennas, and a target outage constraint. In particular, we show that the maximum density

of concurrently transmitting nodes in the network scales linearly with the number of antennas at the transmitter, as the number of antennas increases.

II. SYSTEM MODEL AND PERFORMANCE METRICS

Consider an ad hoc network in which the transmitting nodes are located according to a two-dimensional homogeneous PPP Φ_0 with intensity λ_0 transmitters per unit area. Each transmitter attempts to transmit with a probability P_a , independently of other transmitters, following a slotted ALOHA random access protocol. The process of active transmitters in each slot also forms a homogeneous PPP Φ with intensity $\lambda = \lambda_0 P_a$. The location of the n -th active transmitter is denoted by T_n . Each transmitter communicates with a receiver at a fixed distance d away from it. The receivers are not part of the transmitter PPP. The location of the n -th receiver is denoted by R_n .

By the stationarity of the Poisson process, we consider the performance of a typical transmitter-receiver link, T_0 - R_0 . From the perspective of R_0 and by Slivnyak's theorem [10], the process of interfering transmitters also forms a homogeneous PPP of intensity λ . The transmitting nodes in the network are equipped with N antennas; whereas the receivers have a single antenna. The channel corresponding to the desired signal between T_0 and R_0 is denoted by $\mathbf{h}_0 \in \mathbb{C}^{N \times 1}$. The interfering channel between R_0 and the n -th transmitting node T_n is denoted by $\mathbf{g}_n \in \mathbb{C}^{N \times 1}$. The symbol transmitted from T_n for R_n is given by s_n , such that $\mathbb{E}[|s_n|^2]$ is normalized to one, for all n . We use the simplified attenuation model for the distance-dependent pathloss, $\ell(d_n) = \gamma d_n^{-\alpha}$, where γ is the fixed transmit power at T_n and d_n is the distance between T_n and R_0 . The pathloss exponent is denoted by $\alpha > 2$. The received signal at the tagged receiver R_0 for a frequency flat channel is given by

$$y_0 = \sqrt{\gamma} d^{-\frac{\alpha}{2}} \mathbf{h}_0^* \mathbf{f}_0 s_0 + \sqrt{\gamma} \sum_{T_n \in \Phi} d_n^{-\frac{\alpha}{2}} \mathbf{g}_n^* \mathbf{w}_n r_n + v_0, \quad (1)$$

where the vector $\mathbf{f}_0 \in \mathbb{C}^{N \times 1}$ is the beamforming vector at T_0 , $\mathbf{w}_n \in \mathbb{C}^{N \times 1}$ is the beamforming vector at T_n for all n , and $v_0 \in \mathbb{C}$ is the additive white Gaussian noise at R_0 with variance σ^2 . We assume that the elements of the channel matrices \mathbf{h}_0 and \mathbf{g}_n are independent and identically distributed $\mathcal{CN}(0, 1)$, modeling a richly scattered independent fading environment.

We assume that each transmitter has knowledge of the channel to its intended receiver, and the channels to the adjacent receivers that the transmitter is interfering with. The CSI assumptions in this paper are applicable for time division duplexing (TDD) systems. The same assumptions on the knowledge of the channels at the receiving nodes have been considered in [1], [2], [8].

A primary performance metric of interest in this paper is the probability of outage P_{out} with respect to a predefined

signal-to-interference-plus-noise ratio (SINR) β ,

$$P_{out} = \mathbb{P}(\text{SINR} \leq \beta). \quad (2)$$

The SINR statistics at R_0 depend on the design of the beamforming vectors \mathbf{f}_0 and \mathbf{w}_n , for all n . The probability of outage is used to compute the network throughput. The network throughput is defined as the product of the sum rate per unit area and the probability of success assuming that capacity achieving codes are used. It is given by

$$T = \lambda \log_2(1 + \beta) \mathbb{P}(\text{SINR} > \beta). \quad (3)$$

The network throughput is different from the transmission capacity which is defined as the area spectral efficiency for the maximum density $\lambda_\epsilon = \sup\{\lambda : \mathbb{P}(\text{SINR} \leq \beta) \leq \epsilon\}$ allowed subject to an outage constraint $\epsilon > 0$, i.e.,

$$C = \lambda_\epsilon \log_2(1 + \beta)(1 - \epsilon). \quad (4)$$

In contrast to the network throughput that may result in high outage events, the transmission capacity calculates the maximum density of transmissions per unit area so that a desired outage level ϵ is not exceeded.

III. INTERFERENCE NULLING AT THE TRANSMITTER

We propose a transmission strategy based on ZF interference nulling at the transmitter. We assume that each transmitter employs a partial ZF (PZF) beamforming vector. PZF was first suggested in [1] for receive filter design. It was found to be amenable to analysis and to explicitly balance interference cancellation and boosting of the desired signal power. With PZF, the transmitter uses ℓ degrees of freedom to null its interference to its closest, in terms of distance, receivers, and uses the remaining $N - \ell$ degrees of freedom to transmit the desired signal to its associated receiver. With no interference nulling $\ell = 0$, PZF is equivalent to transmit beamforming; whereas for $\ell = N - 1$ it is equivalent to full zero forcing beamforming.

To illustrate PZF beamforming, let

$$\mathbf{H}_0 = [\mathbf{h}_1 \ \mathbf{h}_2 \ \cdots \ \mathbf{h}_\ell], \quad \ell \leq N - 1$$

be a $N \times \ell$ matrix of channels from T_0 to its closest receivers. The vectors $\mathbf{h}_1, \dots, \mathbf{h}_\ell$ are such that $d_{01} < d_{02} < \dots < d_{0\ell}$ where d_{0n} is the distance from T_0 to receiver R_n . The PZF beamforming vector \mathbf{f}_0 is chosen such that it is in the null space of \mathbf{H}_0 , $\text{Null}(\mathbf{H}_0)$, of dimension $N - \ell$. Furthermore, to maximize the desired signal power, \mathbf{f}_0 is taken in the direction of the projection of the desired channel \mathbf{h}_0 onto $\text{Null}(\mathbf{H}_0)$. More precisely, \mathbf{f}_0 is computed as

$$\mathbf{f}_0 = \mathbf{Q}\mathbf{Q}^* \mathbf{h}_0, \quad (5)$$

where \mathbf{Q} forms an orthonormal basis for $\text{Null}(\mathbf{H}_0)$.

For the proposed spatial interference strategy, the signal-to-interference-plus-noise ratio (SINR) at the tagged receiver

Fig. 1. Partial zero forcing interference nulling at the transmitter. The interference at the tagged receiver R_0 is nulled by its closest interferer T_1 but not nulled by its second interferer T_2 . The cardinality and the location of the cancelled interferers in the set $\{C_t\}$ in the aggregate interference at R_0 is unknown.

R_0 is written as

$$\text{SINR} = \frac{\gamma d^{-\alpha} |\mathbf{h}_0^* \mathbf{f}_0|^2}{\sigma^2 + \gamma \sum_{T_n \in \Phi / \{C_t\}} d_n^{-\alpha} |\mathbf{g}_n^* \mathbf{w}_n|^2} = \frac{|\mathbf{h}_0^* \mathbf{f}_0|^2}{\frac{1}{\text{SNR}} + d^\alpha I_t}, \quad (6)$$

where $\text{SNR} = \frac{\gamma d^{-\alpha}}{\sigma^2}$ is the signal-to-noise ratio at R_0 . The set $\{C_t\}$ is the set of the transmitters that nulled their interference towards R_0 . The cardinality $|C_t|$ of $\{C_t\}$ as well as the location of the nodes in $\{C_t\}$ with respect to R_0 , are unknown. They depend on the density of the nodes λ in the network and the distance from the transmitters to the receiver R_0 . For transmit PZF, interference nulling is done “blindly” towards the closest receivers to the transmitter. The aggregate interference at the tagged receiver R_0 is not taken into account in the nulling performed at T_0 . Consequently, the aggregate interference at R_0 need not be void of the closest ℓ interferers to R_0 as in the case of PZF receiver cancellation [1]. This is illustrated in Figure 1, where T_1 and T_2 are the closest interferers to R_0 , the interference from T_1 is removed at R_0 while that of T_2 remains.

The desired signal power $|\mathbf{h}_0^* \mathbf{f}_0|^2$ is Chi-squared distributed with $2(N - \ell)$ degrees of freedom, $\chi_{2(N-\ell)}^2$. This follows from the projection of a random vector \mathbf{h}_0 onto an independent $(N - \ell)$ -dimensional space $\text{Null}(\mathbf{H}_0)$. The distribution of the aggregate interference term depends on the characterization of the set $\{C_t\}$. We compute an upper bound on the expected value of the interference in the following Lemma.

Lemma 1: The expected interference power I_t at R_0 is given by

$$\mathbb{E}[I_t] = (\pi d^2 \lambda_p)^{\frac{\alpha}{2}} \left(\frac{\alpha}{2} \left(\frac{\alpha}{2} - 1 \right)^{-1} \right), \quad (7)$$

where $\lambda_p = \lambda - \rho\ell$, and ρ is the inverse of the area occupied

by the interferers on the two-dimensional network space.

Proof: The proof is provided in Appendix A. ■

The upper bound on $\mathbb{E}[I_t]$ can be understood by arguing that on average each receive node in the network receives interference from all the transmitters except ℓ interferers, chosen at random from the total set of interferers Φ . This implies that the density of interferers is reduced by $\rho\ell$ where ρ is the inverse of the area occupied by the network. The value of ρ does not affect the conclusions drawn on the scaling performance of the network.

Using the distribution of the desired signal power, and the upper bound on the expected interference term, we find an upper bound on the probability of outage for transmit PZF.

Theorem 1: The probability of outage for transmit ZF beamforming for an ad hoc network with PPP distributed nodes with density λ and N transmit antennas is upper bounded by

$$P_{\text{out}}^{\text{T-PZF}} \leq \frac{\beta \left(\frac{\alpha}{2} \left(\frac{\alpha}{2} - 1 \right)^{-1} (\pi d^2 (\lambda - \rho\ell))^{\frac{\alpha}{2}} + \frac{1}{\text{SNR}} \right)}{N - \ell - 1}. \quad (8)$$

Proof: We apply the Markov inequality on the tail probability of the inverse SINR to get

$$\begin{aligned} \mathbb{P}[\text{SINR} \leq \beta] &= \mathbb{P}\left[\frac{1}{\text{SINR}} \geq \frac{1}{\beta}\right] \leq \beta \mathbb{E}\left[\frac{1}{\text{SINR}}\right] \\ &\stackrel{(a)}{=} \beta \mathbb{E}\left[\frac{1}{|\mathbf{h}_0^* \mathbf{f}_0|^2}\right] \left[\mathbb{E}\left[\frac{1}{\text{SNR}}\right] + \mathbb{E}[d^\alpha I_t] \right] \\ &\leq \frac{\beta \left(\frac{\alpha}{2} \left(\frac{\alpha}{2} - 1 \right)^{-1} (\pi d^2 \lambda_p)^{\frac{\alpha}{2}} + \frac{1}{\text{SNR}} \right)}{N - \ell - 1}. \end{aligned}$$

The expression in (a) is obtained because the signal and interference plus noise terms are independent. The expected value of the desired signal power is given by $N - \ell - 1$. The upper bound on the probability of outage is finally computed using the upper bound from Lemma 1. ■

A bound on the network throughput T is obtained from the complement of the probability of outage as follows

$$\begin{aligned} T \geq & \left[1 - \frac{\beta \left(\frac{\alpha}{2} \left(\frac{\alpha}{2} - 1 \right)^{-1} (\pi d^2 (\lambda - \rho\ell))^{\frac{\alpha}{2}} + \frac{1}{\text{SNR}} \right)}{N - \ell - 1} \right] \\ & \times \lambda \log_2(1 + \beta). \end{aligned} \quad (9)$$

The transmission capacity C is a function of the maximum density λ_ϵ such that the probability of outage is less than a threshold ϵ . A lower bound on the maximum density is obtained by setting the probability of outage expression in Theorem 1 equal to ϵ and solving for λ . It is given by

$$\lambda_\epsilon \geq \left(\frac{(N - \ell - 1)\epsilon - \frac{\beta}{\text{SNR}}}{\beta(\pi d^2)^{\frac{\alpha}{2}} \frac{\alpha}{2} \left(\frac{\alpha}{2} - 1 \right)^{-1}} \right)^{\frac{2}{\alpha}} + \rho\ell. \quad (10)$$

In what follows, we use the bound on the transmission capacity to derive the main result on the scaling of the transmit PZF beamforming system with the number of transmit antennas.

IV. LINEAR DENSITY SCALING

To establish the scaling of the density λ_ϵ with the number of transmit antennas N for transmit PZF beamforming, we choose the number of nulled receivers ℓ to be a constant fraction of the total number of antennas

$$\ell = \theta N, \quad 0 < \theta < 1.$$

We rewrite the lower bound on the density λ_ϵ in terms of θ as

$$\lambda_\epsilon \geq \left(\left(\frac{\epsilon}{\beta} \right)^{\frac{2}{\alpha}} \frac{(\frac{\alpha}{2} - 1)^{\frac{2}{\alpha}} (\frac{2}{\alpha})^{\frac{2}{\alpha}}}{\pi d^2} (1 - \theta)^{\frac{2}{\alpha}} \left(1 - \frac{1 + \frac{\beta}{\text{SNR}}}{(1 - \theta)N} \right)^{\frac{2}{\alpha}} + \rho \theta N^{1 - \frac{2}{\alpha}} \right) N^{\frac{2}{\alpha}}. \quad (11)$$

As the number of antennas N increases, for sufficiently large N , the lower bound on λ_ϵ scales linearly with N . More formally, as $N \rightarrow \infty$,

$$\frac{\lambda_\epsilon}{N} \geq \rho \theta. \quad (12)$$

This shows linear scaling of the density λ_ϵ with the number of transmit antennas when transmit ZF beamforming is employed. The linear scaling result can be understood by considering Lemma 1, as on average the aggregate interference power at R_0 is reduced by $\ell = \theta N$. This provides a linear scaling of the interference term with N . Similarly, the desired signal power increases linearly with N . The signal and interference terms both increase with the same scaling with N and thus the linear scaling is maintained for sufficiently large N .

V. SIMULATION RESULTS AND DISCUSSION

In this section, we present Monte Carlo simulations to evaluate the performance of the transmit ZF scheme proposed in the paper. The simulation setup follows that in [3]. The distance between each transmitter and its associated receiver is $d = 10$ m, and the pathloss exponent is set to $\alpha = 4$. The probability of outage threshold β is taken equal to 3 corresponding to an SINR threshold value of 4.8 dB.

Figure 2 plots the density λ_ϵ of transmitting nodes on a log-log scale for increasing number of transmit antennas N , for $\epsilon = 0.1$. It compares the numerically computed density, with the lower bound obtained in Theorem 1, and the lower bound obtained in [1] for ZF interference cancellation at the receiver for a single input multiple output (SIMO) system, with N receive antennas. We observe from the figure that the bounds and the numerically computed density indeed show a linear scaling of λ_ϵ with N . The lower bound of Theorem 1 is tighter for a small number of antennas. The plot also suggests that the simulated transmit ZF beamforming density scaling approaches the bound for the SIMO interference cancellation scheme, as the number of antennas increases.

In Figure 3, the network throughput is plotted for an increasing number of antennas N , and an outage probability

Fig. 2. The maximum density of transmitting nodes λ_ϵ versus the number of transmit antennas N . The simulated density refers to the density scaling obtained by Monte Carlo simulations for $\epsilon = 0.1$. The analytical transmit nulling density refers to the density obtained in Theorem 1. The receiver cancellation density is obtained in [1].

Fig. 3. The network throughput as a function of the number of antennas N for MISO ZF transmit nulling and SIMO ZF receive cancellation in [1].

target $\epsilon = 0.1$. The network throughput achieved using transmit ZF beamforming is compared with that of the SIMO interference cancellation scheme in [1]. Figure 3 shows that the two network throughputs are almost equivalent. This clearly illustrates that receive processing techniques, while achieving good performance, should not be considered in exclusivity when it comes to interference reduction in multiple antenna ad hoc networks. Transmit processing using a “blind” interference nulling strategy yields good performance, and removes the processing burden from the receiver.

Finally, although linear density scaling is shown to be achieved for any $0 < \theta < 1$ for transmit PZF, we can find the optimal fraction of antennas θ that should be used at the transmitter to null the interference, while maximizing the density of concurrent transmitters in the network. Figure 4 plots λ_ϵ versus the number of nulled interferers ℓ for $N = 10$ and $\epsilon = 0.1$. The maximum density is shown to be achieved at $\ell = 5$ for $\alpha = 4$. This agrees with the optimal fraction $\theta^* = 1 - \frac{2}{\alpha}$ obtained for ZF interference cancellation in [1].

Fig. 4. The maximum density λ_ϵ versus the number of nulled receivers ℓ for $N = 10$, $\epsilon = 0.1$ and $\alpha = 4$. The maximum is reached at $\ell = 5$.

VI. CONCLUSION

In this paper, we analyzed spatial interference mitigation for a MISO ad hoc network. We showed that ZF interference nulling at the transmitter provides a linear increase in the transmission capacity with the number of antennas at the transmitter, for a given outage constraint. Although transmit PZF is applied towards the closest receivers, which do not necessarily correspond to the closest interferers to the desired receiver, its network throughput performance is comparable to the performance of SIMO ZF cancellation, where cancellation is done deterministically towards the closest interferers at the receiver. The main takeaway from this paper is that multiple antennas at the transmitter should be used more efficiently to improve the throughput performance of mobile ad hoc networks. Future work includes devising a distributed multiple input multiple output interference mitigation strategy, where in addition to interference nulling at the transmitter, antennas at the receiver are used to cancel residual interference.

APPENDIX A PROOF OF LEMMA 1

The expected value of the aggregate interference I_t is given by

$$\begin{aligned} \mathbb{E} \left[\sum_{T_n/\{C_t\}} d_n^{-\alpha} |\mathbf{g}_n^* \mathbf{w}_n|^2 \right] &= \sum_{T_n/\{C_t\}} \mathbb{E} [d_n^{-\alpha} |\mathbf{g}_n^* \mathbf{w}_n|^2] \\ &= \sum_{T_n/\{C_t\}} \mathbb{E} [d_n^{-\alpha}] \end{aligned}$$

The distances d_1^2, d_2^2, \dots form a one dimensional PPP with intensity $\pi\lambda_p$. The density λ_p is written as a function of λ as follows

$$\lambda_p = \lambda - \rho\ell, \quad (13)$$

where ρ is the inverse of the area occupied by the interferers, or the two dimensional space of the ad hoc network. The random variables $\pi\lambda_p d_n^2$ are distributed as χ_{2n}^2 , and thus have

PDF $f(x) = \frac{x^{n-1}e^{-x}}{(n-1)!}$. Therefore

$$\mathbb{E} [d_n^{-\alpha/2}] = (\pi\lambda_p)^{\frac{\alpha}{2}} \frac{\Gamma(n - \alpha/2)}{\Gamma(n)}. \quad (14)$$

This quantity is finite only for $n > \frac{\alpha}{2}$, and thus the expected power from the nearest uncanceled interferer is finite only if $n > \frac{\alpha}{2}$. The upper bound on the expected interference, for $n \geq \lceil \frac{\alpha}{2} \rceil$, is given by,

$$\begin{aligned} \mathbb{E}[I_t] &= (\pi\lambda_p)^{\frac{\alpha}{2}} \sum_{n=\lceil \frac{\alpha}{2} \rceil}^{\infty} \frac{\Gamma(n - \frac{\alpha}{2})}{\Gamma(n)} \\ &\stackrel{(a)}{<} (\pi\lambda_p)^{\alpha/2} \left(1 + \sum_{n=\lceil \frac{\alpha}{2} \rceil+2}^{\infty} \left(n - \lceil \frac{\alpha}{2} \rceil \right)^{-\frac{\alpha}{2}} \right) \\ &\stackrel{(b)}{\leq} (\pi\lambda_p)^{\frac{\alpha}{2}} \left(1 + \int_{\lceil \frac{\alpha}{2} \rceil+1}^{\infty} \left(x - \lceil \frac{\alpha}{2} \rceil \right)^{-\frac{\alpha}{2}} dx \right) \\ &= (\pi\lambda_p)^{\frac{\alpha}{2}} \left(\frac{\alpha}{2} \left(\frac{\alpha}{2} - 1 \right)^{-1} \right) \end{aligned} \quad (15)$$

where (a) is reached by invoking Kershaw's inequality on the Gamma function [3],

$$\frac{\Gamma(i - \alpha/2)}{\Gamma(i)} < \left(i - \lceil \frac{\alpha}{2} \rceil \right)^{-\frac{\alpha}{2}},$$

and (b) is computed by upper bounding the summation by the integration.
