In this paper, we describe the research results for learning such a mapping from data, recorded during some human-human interactions, so as to implement, in the IM, a behavior similar to the one of a human. An imitation learning method is thus adopted. Especially, structured classification is investigated and proven to efficiently learn a behavior similar to human users where the similarity between human and algorithms is measured via a new criterion called Naturalness and defined in Sec. 5. In addition, we use a technique of boosting for the structured classification algorithm which makes it a non-parametric algorithm. This avoids the choice of meta-parameters. Finally, we test different imitation algorithms on data sets of real laughs in a natural interaction context which is the yes/no game described in Sec. 4.

2. IMITATION LEARNING

Describing the optimal behavior of the avatar is a very tricky task. It would require the perfect knowledge of rules prevailing to the generation of laughter by humans. Interpreting sources of laughter or predicting laughter from a cognitive or psychology perspective is non-trivial. Therefore, a data-driven method has been preferred here. Especially, learning by imitation seems the best suited framework to learn the IM policy. Indeed, humans are implementing such a policy and they can provide examples of natural behaviors.

Formally, in the learning by imitation framework, an artificial learning agent (here the IM) learns to behave optimally by observing an expert agent demonstrating the task. The expert is implementing an optimal policy \( \pi^* \) and the demonstrations provide a set of examples \( \{s_i, a_i = \pi^*(s_i)\}_{1 \leq i \leq N} \). The problem is thus to learn a policy \( \hat{\pi} \) such that \( \forall s, \hat{\pi}(s) \approx \pi^*(s) \) from the set of demonstrations.

One way to address the problem of imitation learning is to reduce it to a Multi-Class Classification (MCC) problem \[5\] \[6\] \[7\] \[8\]. The goal of MCC is, given a training set \( D = \{(s_i, a_i) \}_{1 \leq i \leq N} \) where \( S \) is a compact set of inputs (generally a compact set of \( \mathbb{R}^n \)) and \( A \) a finite set of labels, to find a decision rule \( \pi \in A^S \) that generalizes the relation between inputs and labels. More formally, it consists in finding a decision rule \( \pi \in H, \) where \( H \subset \mathbb{R}^{S \times A} \) is called the hypothesis space, that tries to minimize the following empirical risk:

\[
T(\pi) = \frac{1}{N} \sum_{i=1}^{N} \sum_{a \neq a_i} 1_{\{s_i, a\}}.
\]

where \( 1_{\{s, a\}} = 1 \) if \( a \neq b \) and 0 otherwise.

A large literature already exists about the MCC problem. Well-known methods such as Classification Trees \[9\], K-Nearest Neighbors (KNN) \[10\] and Support Vector Machines (SVM) \[11\] \[12\] are widely used and statistically studied. In \[5\], the authors use an arti-
cial neural network to learn a driving policy for a robotic vehicle. Neural nets are also used in [7] to learn to play video games (although the method is more generic and could use other MCC methods). KNN’s where used in [2] in a similar application as the one described in this paper. In [9], structured classification [14] is used to learn a grasping control policy for a robotic arm.

3. STRUCTURED CLASSIFICATION FOR IMITATION LEARNING

In [6], the authors use a large margin approach which allows adding some prior (or structure) via a margin function in the classification method. That is why it is considered as a structured classification method. The large margin approach is a score-based MCC where the decision rule $\pi \in A^S$ is obtained via a score function $q \in \mathbb{R}^{S \times A}$ such that $\forall s \in S, \pi(s) = \arg\max_{a \in A} q(s, a)$. The large margin approach consists, given the training set $D$, in solving the following optimization problem:

$$q^* = \arg\min_{q \in \mathbb{R}^{S \times A}} J(q),$$

$$J(q) = \frac{1}{N} \sum_{i=1}^{N} \max_{a \in A} \{q(s_i, a) + l(s_i, a_i, a)\} - q(s_i, a_i),$$

where $l \in \mathbb{R}^{S \times A}$ is called the margin function. If it is zero, minimizing $J(q)$ attempts to find a score function $q^*$ for which the example labels are scored higher than all other labels. Choosing a nonzero margin function improves generalization [6]. Instead of requiring only that the demonstrated label is scored higher than all other labels, it requires it to be better than each label by a margin given by the margin function. Thus, the margin function allows deciding which samples are required to be well classified by putting an important margin on this particular example compared to the others. The policy outputted by this algorithm would be $\pi(s) = \arg\max_{a \in A} q(s, a)$ where $q$ is the output of the minimization of $J(q)$. The advantages of this method are its simplicity and the possibility to change the margin that allows us to adapt to specific characteristics of the problem. In addition, in [14], the authors use a boosting technique to solve the optimization problem given by Eq. (1) which is advantageous. A boosting method is an interesting optimization technique: it minimizes directly the criterion in Eq. (1) without the step of choosing features. As presented in [15], a boosting algorithm is a projected sub-gradient descent [16] of a convex functional (here $J$ is convex relatively to the variable $q$) in a specific functions space (here $\mathbb{R}^{S \times A}$) which has to be a Hilbert space. Boosting algorithms use a projection step on a restriction of sets when optimizing over functions space, because the functions representing the gradient are often computationally difficult to manipulate and do not generalize well to new inputs [15]. In boosting literature, the restriction set corresponds directly to the set of hypotheses generated by a weak learner. In our experiments, we choose as restriction set the set of classification trees with two classes.

4. EXPERIMENTAL SETUP

The yes/no game is one of the possible scenarios of an interaction between humans and avatars where laughter is involved. In this game, players must respond to questions without saying “yes” or “no”. The experiment scenario we present in this article is illustrated in Fig. 2. Two users are sitting on one side of a table while a virtual agent projected on a large screen is placed on the opposite side of the table. The users start to play the yes/no game, one asking questions (e.g., “what’s your nationality?”, “are you sure?”), this user is named $U_1$, and the other one answering trying to avoid to say “yes” or “no” (e.g., “I’m not sure” or “definitely”), this user is named $U_2$. The avatar, named $A$, participates to the interaction by laughing and asking questions. Of course, $U_1$ and $A$ try to make $U_2$ to say “yes” or “no” and thus try to induce a loss of self-control. At any point, laughter can occur for any participant. The avatar has to generate laughter at appropriate moments given its perception of the context.

As shown in Fig. 2 detection of humans’ laughter is performed through body (Kinect and body markers), face (Kinect) and speech (head mounted microphones) analysis [17]. Several recognition algorithms are executed in real-time to determine users’ expressivity of motion.

In order to train our avatar by an imitation learning algorithm, several experiments are first recorded, where the avatar (symbolized by a screen in Fig. 2) is replaced by a human playing the role of the avatar (this is the expert we want to imitate). The same detection material as for the two other participants is used for the human playing the role of the avatar. Thanks to those recordings an expert data set $D = \{s_i, a_i = \pi(s_i)\}_{1 \leq i \leq N}$ is generated which is the input of an imitation learning algorithm. Indeed, for each user ($U_1$ and $U_2$), the recognition algorithms are able to extract each 0.5s a 4 features which are real values between 0 and 1. The 4 features are the probability of speech, the probability of laughter, the intensity of laughter and the probability of smile. Moreover, another feature, which represents the context of the game, is added by annotation of the recordings: 0 when the game is currently ongoing and 1 when it ends (that is when $U_2$ said “yes” or “no” or that some time-out occurred). Thus each 0.5s, we are provided 9 features (4 features for $U_1$, 4 features for $U_2$ and the context) that represents the state of the game $s_i$. Finally, by annotations of the recordings, we provide each 0.5s a binary information (1 or 0) giving the decision of the expert ($a_i$): laugh/no_laugh (so it is a 2 actions decision process). A sample $(s_i, a_i)$ where $a_i \neq 0$ corresponds to a no_laugh sample and a sample $(s_i, a_i)$ where $a_i = 1$ corresponds to a laugh sample. In addition, we also collect, by annotations, the binary laugh/no_laugh information for $U_1$ and $U_2$: $(a_i^{U_1}, a_i^{U_2})_{1 \leq i \leq N}$. Now that we have the expert data set, it is possible to use it as an input to different imitation learning algorithms.
In this section, we present the results obtained by applying different imitation learning algorithms to the expert data set. We use 4 different algorithms, 3 classical classification algorithms, which are KNN, Classification Tree and SVM, and the large-margin algorithm presented in Section 3. The KNN algorithm was previously used in [2], where we do the same choice in order to compare to other methods. The SVM algorithm uses a Gaussian kernel with a standard deviation $\sigma = 1$ and the Classification Tree is a pruned binary classification tree. For the large margin approach, we choose a margin with a particular structure that favors the no_laugh samples more than the laugh samples so as to only synthesized laughter when it is really appropriate. Indeed, laughing at inappropriate moments seems awkward for humans and it is important to avoid that while not laughing is not too problematic in this application. Thus, we choose the following margin structure:

$$l(s_i,a_i,a) = 0 \text{ if } a = a_i,$$

$$l(s_i,a_i,a) = 6 \text{ if } a \neq a_i \text{ and } a_i = 0, \text{ (no laugh)}$$

$$l(s_i,a_i,a) = 1 \text{ if } a \neq a_i \text{ and } a_i = 1, \text{ (laugh)}.$$

Eighteen minutes of recordings were collected in three sessions where the game was played several times (at least twice by recordings). This provided an expert data set $D = \{s_i,a_i = \pi^p(s_i)\}_{1 \leq i \leq N}$ of 2285 examples (that is the number of 0.5s frames). The 4 algorithms were trained on this data set. In order to compare the performances of the algorithms, we use a $P$-fold cross-validation. In $P$-fold cross-validation, the original data set $D$ is partitioned into $P$ equal size sub-samples $D = \{D_p\}_{1 \leq p \leq P}$, where $D_p = \{s_{j,p},a_{j,p} = \pi^p(s_{j,p})\}_{1 \leq j \leq N_p}$ and $\sum_{p=1}^P N_p = N$. Of the $P$ sub-samples, a single sub-sample is retained as the validation data for testing the algorithm, and the remaining $P - 1$ sub-samples are used as training data. The cross-validation process is then repeated $P$ times (the folds), with each of the $P$ sub-samples used exactly once as the validation data. The $P$ results from the folds then can be averaged to produce a single estimation. For each sub-sample $D_p$, and each algorithm algd, we define the policy $\pi^p_{\text{algd}} \in A^9$ learned on the remaining $P - 1$ sub-samples. In addition, we define, for each sub-sample $D_p$, the number of laugh samples $N^\text{laugh}_p = \sum_{j=1}^{N_p} 1\{a_{j,p}=1\}$ and the number of no_laugh samples $N^\text{no_laugh}_p = N_p - N^\text{laugh}_p$. Several quality evaluation criteria were used for each algorithm. The first criterion is the mean over the $P$ folds of the classification rate:

$$\frac{1}{P} \sum_{p=1}^P \frac{1}{N_p} \sum_{j=1}^{N_p} 1\{\pi^p_{\text{algd}}(s_{j,p})=a_{j,p}\}.$$

The second criterion is the mean over the $P$ folds of the classification rate on laugh samples:

$$\frac{1}{P} \sum_{p=1}^P \frac{1}{N_p^\text{laugh}} \sum_{j=1}^{N_p^\text{laugh}} 1\{\pi^p_{\text{algd}}(s_{j,p})=a_{j,p}\} 1\{a_{j,p}=1\}.$$

The third criterion is the mean over the $P$ folds of the classification rate on no_laugh samples:

$$\frac{1}{P} \sum_{p=1}^P \frac{1}{N_p^\text{no_laugh}} \sum_{j=1}^{N_p^\text{no_laugh}} 1\{\pi^p_{\text{algd}}(s_{j,p})=a_{j,p}\} 1\{a_{j,p}=0\}.$$

We choose those different criteria in order to see the quality of each algorithm on the laugh samples and the no_laugh samples because those two classes are not well balanced (basically there is 5 times more no_laugh samples than laugh samples). Table 1 contains the results of the different algorithms in terms of classification rates with $P = 5$.

The Large Margin has the best results for the global classification rate and the no_laugh rate. The structure of the margin favors the performance on the no_laugh samples and it is reflected in the results. KNN works well on the laugh samples which is also the case of the Classification Tree but has a really poor global performance. It seems that the avatar is too reactive (laughs too often) which can be problematic if the laughs happen on inappropriate moments: this behavior appears unnatural. In order to check if the good performance on laughs of KNN is due to the fact that it is too reactive, we computed the number of laughs produced for each fold and took the mean. Results are provided in Table 2.

The Classification Tree and the KNN avatar are too reactive which can explain their good performance on laughs but their behavior is not natural compared to the expert. The most natural behavior is the one produced by the Large Margin algorithm which laughs in the same proportion than the expert. So the classification rates are not appropriate measures to assess the algorithms according to this application.

For this reason, we came up with a measure for naturalness which indicates if the policy produced by the algorithm corresponds

\begin{table}[h]
\begin{center}
\begin{tabular}{|c|c|c|c|}
\hline
Algorithms & Global & laugh & no_laugh \\
\hline
Large Margin & 0.6871 & 0.3256 & 0.8081 \\
SVM & 0.6723 & 0.3106 & 0.7893 \\
KNN & 0.5440 & 0.6347 & 0.5173 \\
Tree & 0.5570 & 0.5106 & 0.5732 \\
\hline
\end{tabular}
\end{center}
\caption{Classification rates.}
\end{table}

\footnote{The variable algo can take the values KNN, SVM, LargeMargin and Tree.}
to the behavior of the expert. The idea is to compare if relatively to the two other users the human playing the avatar and the algorithm have the same behavior.

In order to see if there is a similarity between the behavior of the user playing the avatar $A_{\text{expert}}$ and the one learnt by the algorithms $A_{\text{algo}}$, we check if the behavior of the expert $A_{\text{expert}}$ compares to the users ($(U_q)_{q=1,2}$) similarly to the way the avatar’s behaviour $A_{\text{algo}}$ compares to the users ($(U_q)_{q=1,2}$). The idea is to show that the avatar doesn’t differ more from $U_1$ and $U_2$ than the expert does. To do so, for each user $U_q$ and each sub-sample $D_p$, we define the number of laugh samples $N_{\text{laugh}}^{\text{p,q}} = \sum_{j=1}^{N_p} 1_{\{s_{j,p} = l_q\}}$ and the number of no laugh samples $N_{\text{no laugh}}^{\text{p,q}} = N_p - N_{\text{laugh}}^{\text{p,q}}$. Three criterions were used: the global rate, the laugh rate and no laugh rate. The global criterion rate is the rate of agreement in terms of actions between one of the user and an avatar sample by sample:

$$\frac{1}{2} \sum_{q=1}^{2} \sum_{p=1}^{P} \frac{1}{N_p} \sum_{j=1}^{N_p} 1_{\{s_{j,p} = l_q\}}$$

where $s_{p}^{\text{Expert}}(s_{j,p}) = \pi^{E}(s_{j,p}) = a_{j,p}$. The laugh criterion rate gives the rate of agreed laughs between the avatar and one of the users:

$$\frac{1}{2} \sum_{q=1}^{2} \sum_{p=1}^{P} \frac{1}{N_p} \sum_{j=1}^{N_p} 1_{\{s_{j,p} = l_q\}}$$

The no laugh criterion rate gives the rate of agreed no laughs between the avatar and one of the users:

$$\frac{1}{2} \sum_{q=1}^{2} \sum_{p=1}^{P} \frac{1}{N_p} \sum_{j=1}^{N_p} 1_{\{s_{j,p} = n_q\}}$$

In order to have a single number representing the similarity between the expert avatar $A$ and the avatars outputted by the algorithms, a new criterion, called Naturalness $N_{\text{algo}}$, is defined as follows:

$$N_{\text{algo}} = \prod_{i=1}^{3} \frac{\min(rate_{\text{algo}}^{i}, rate_{\text{Expert}}^{i})}{\max(rate_{\text{algo}}^{i}, rate_{\text{Expert}}^{i})}$$

This criterion is thus a measure of the deviation between the behavior of the expert avatar and the behavior learnt by a given algorithm. If the Naturalness is equal to 1, it means that the avatar has the same behavior as the expert relatively to the other users and if it is equal to zero, it means that the avatar has a completely different behavior than the expert.

Table 2 gives the results. The Large Margin method clearly outperforms the other ones, which means that its behavior relatively to the other users corresponds closely to the one of the expert. We see that the KNN and the Tree have poor Naturalness as they laugh too much relatively to the other users which is not what the expert does.

### 6. CONCLUSION AND PERSPECTIVES

In this paper, a method for learning when an avatar should laugh during an interaction with humans was presented. It is based on a data-driven imitation learning algorithm and especially on structured classification method. The structured margin implied in this method is used to weight the importance of laughter compared to silence so as to generate a more natural behaviour and deal with the unbalanced nature of data. It is shown, in a yes/no game setting, that the method outperforms other classification methods in terms of overall similarity with a human. Compared to previous experiments [2], this method objectively provides better results in terms of a newly introduced criterion.

Here, imitation learning is reduced to a multiclass classification problem. Yet, imitation learning can also be solved by other methods such as inverse reinforcement learning [18, 19]. Actually, this method has been shown to work better for some types of problems [20] and has already been used to imitate human users in the case of spoken dialogue systems [21]. Therefore, we plan to extend this work to inverse reinforcement learning in the near future. Also, this method could be used to generate new simulation techniques for optimizing human machine interaction managers in other applications such as spoken dialogue systems [22, 23].
